High-quality datasets are needed to understand how global and local properties of protein-protein interaction, or ‘interactome’, networks relate to biological mechanisms, and to guide research on individual proteins. In an evaluation of existing curation of protein interaction experiments reported in the literature, we found that curation can be error-prone and possibly of lower quality than commonly assumed.

An essential component of systems biology is discovery of the network of all possible physical protein-protein interactions (PPIs), the ‘interactome’ network1–3. There are two complementary ways to obtain comprehensive PPI information. One is to systematically test all pairwise combinations of proteins for physical interactions at proteome scale with a high-throughput assay3. The alternative is to curate all publications in the literature, each describing one (or a few) PPI(s) assayed at low throughput4, and then make the curation accessible in interaction databases. As neither strategy can come close to allowing us to discover the full interactomes yet5–7, the matter arises as to which strategy can best fill in the missing pieces.

High-throughput protein interaction assays

Two approaches are in frequent use for high-throughput mapping of protein interactions at proteome scale. Yeast two-hybrid assays attempt to identify binary interactions8,9, whereas co-affinity purification followed by mass spectrometry identifies presence in a protein complex10 but may not accurately determine the binary interactions between proteins within a complex7. Other technologies exist for mapping both binary interactions and presence in the same complex11, but none can yet be routinely scaled up for high-throughput assays, although recently, a protein complementation assay allowed a large-scale mapping of the yeast interactome12.

Curating protein interactions

Manual curation of protein interactions from literature began with pioneering curation for the yeast Saccharomyces cerevisiae by the Yeast Proteome Database (YPD)13. Those early efforts demonstrated that effective curation was possible and also broadly aimed to capture all types of functional and genomic information, not only PPIs. Genomic databases dedicated to a single model organism arose in parallel with genome sequencing projects, for example, the Saccharomyces Genome Database (SGD)14 and The Arabidopsis Information Resource (TAIR)15. Although initially devoted to sequence information, many of these databases eventually added many types of literature-curated information, including PPI data.

In time, the publications reporting PPIs exceeded the capacity of specialized genome databases and led to
Interologs are in silico predictions of protein interactions in one species between a pair of proteins whose orthologs are known to interact in another species. The assumption that interologs are more likely true than not is widely held. Recent evaluations have now revisited this assumption in several ways.

The most important question is where to draw the line for interspecies transfer. For instance, is mouse-human transfer close enough but more evolutionary distant mammals not close enough? Actually, it is not the species relatedness but the sequence relatedness that really matters. Interolog transfers are only accurate for especially high sequence similarity. Hence, interolog predictions with low sequence conservation should not be accepted, even between closely related species.

Investigations of intrinsic disorder in proteins have also unsettled the certainty that protein interactions are highly conserved. There are two types of interacting surfaces in proteins: domain-domain interactions are more prevalent in stable protein complexes, whereas domain-disorder interactions are more transient. Domain-disorder interactions evolve much faster than domain-domain interactions. The proportion of protein interactions that are of the domain-disorder type versus the domain-domain type is not known, even approximately, for any species. Still, the likely considerable proportion of poorly conserved domain-disorder interactions means that the proportion of nonconserved interactions is substantial.

In the one experimental test of interologs so far, only one-third of the sample set of yeast interactions found by yeast two-hybrid were reproduced by yeast two-hybrid between the C. elegans orthologs. Perhaps the large evolutionary distance between yeast and worm precluded a higher success rate, and mouse-human interologs might have a better success rate, but that supposition has not been experimentally tested.

In light of all these reappraisals, curation policies are changing. For instance, one interaction database has stopped transferring nonhuman interactions to human, a change from earlier practice. Other interaction databases may follow suit. Alternatively, those interactions predicted by interolog extrapolation could be explicitly delineated in databases from those experimentally demonstrated, so the user could choose the appropriate data to examine. Either policy becomes complicated because species of the interactors are not often provided in publications. Overall, it would seem best practice to only curate the species for which there is direct experimental evidence; in reality, doing so is difficult.

Completeness and replication of literature-curated datasets

As PPIs supported by multiple publications should be more reliable than those supported by only a single publication, we assessed the proportion of multiply supported PPIs for yeast. We ranked the 11,858 literature-curated yeast PPIs in BioGRID21 (LC-all downloaded in mid-2007). Only 25% of LC-all PPIs have been described in multiple publications (Fig. 1), with just 5% and 2% of these pairs described in ≥3 or ≥5 publications, respectively. More than 75% of LC-all PPIs were thus described in a single publication. Consistent with this low portion of multiply supported PPIs, experimental retests have demonstrated a significantly lower quality for singly supported versus multiply supported literature-curated PPIs for yeast.

Similar investigations for human and for Arabidopsis thaliana showed comparably low proportions of multiply supported PPIs. In the initial search space of ~7,000 × 7,000 genes for a first-draft human interactome mapping project, there are 4,067 binary literature-curated interactions31. Only 15% of these PPIs have been described in multiple publications (Fig. 1), with just 5% and 1% described in ≥3 or ≥5 publications, respectively. More than 85% of human PPIs in the literature-curated set are supported by a single publication, greater than the 75% for yeast. The set of Arabidopsis PPIs was collected from the only two protein-interaction databases that curate Arabidopsis protein interactions, TAIR15 and IntAct20. The Arabidopsis PPI dataset has fewer interactions supported by data in multiple manuscripts than yeast or human (Fig. 1), with just 1% and 0.1% described in ≥3 or ≥5 publications, respectively, with 93% of available Arabidopsis literature-curated PPIs supported by data in only a single publication. All told, the number of PPIs supported by data in multiple publications is small.

Literature-curated datasets are reported to be composed primarily of small-scale experiments. To assess the presumption that PPI databases are small-scale, we measured the proportion of total PPIs identified in high-throughput experiments. For yeast, we ranked the 8,933 interactions supported by data in a single publication by the number of distinct PPIs reported in each corresponding publication (Fig. 2a). More than 60% of protein pairs were curated from manuscripts that described more than 10 interactions, all extracted from 6% of all the manuscripts curated. One-third of the total interactions came from less than 1% of all manuscripts that each describe 100 or more interactions (Fig. 2a), which would reasonably be considered high-throughput. Thus, the yeast literature-curated dataset of PPIs supported by a single publication record is not composed solely of validated interactions from small-scale studies but has a marked portion of PPIs derived from high-throughput experiments. We similarly analyzed a dataset of human curated PPIs31 and found that this human PPI dataset is predominantly low-throughput (Fig. 2b), possibly because at the time these PPIs had been downloaded from the databases few medium- to high-throughput experiments had been published. For Arabidopsis, the proportion of the total literature-curated interactions derived from medium to high-throughput manuscripts is about the same as for yeast (Fig. 2c). In sum, many available literature-curated PPI datasets are populated widely by PPIs from high-throughput experiments.

As an assessment of the completeness for literature-curated datasets is not possible (Table 1), we evaluated database overlaps as a surrogate for completeness, on the argument that different PPI databases should curate from the same set of PubMed reports. BioGRID reports the greatest completeness for yeast but is not yet a participating member of the International Molecular Exchange (IMEx) consortium33,34, so we could not use this database for this analysis. The three IMEx members that do substantial curation of yeast PPIs (MINT, IntAct and DIP) had surprisingly low overlap of curated PPIs (Fig. 3a). That the overlap is so small after years of intense curation of protein interactions is reason for concern. The small overlap is not due to differential curation of high-throughput data, as removal of the six largest PPI reports35–40 still left small overlaps, especially of IntAct with the other two databases (Fig. 3a).

Are the small overlaps due to curating different manuscripts or to differential curation of data from overlapping sets of manuscripts? The answer seems to be that vastly different sets of manuscripts are curated because the curation of PubMed reports also shows small overlap (Fig. 3b). For multiply supported interactions (those reported in two or more published studies), the low overlap remains (Fig. 3c), though the number of interactions drops greatly. Hence even the most heavily investigated interactions, those most likely to be multiply curated, do not seem to be comprehensively covered. In sum, surrogate estimates of completeness of literature-curated datasets, at least for yeast, suggest that coverage of curated literature is far from comprehensive.

These investigations suggest, but in no way demonstrate, that literature-curated PPIs may not have the high reliability often attributed to them. There has not yet been any intensive investigation of the actual reliability of literature-curated PPI datasets. To do so, we recurated representative samples of existing literature-curated PPI datasets for three model organisms—yeast (Saccharomyces cerevisiae), human and plant (Arabidopsis thaliana)—and found that the literature curation of PPI publications can be less than impeccable.

Estimating curation reliability by recuration

For yeast, we recurated in detail 100 randomly selected pairs from the yeast dataset of singly supported interactions (Fig. 1). After evaluating several relevant criteria, we assigned each interaction a score of 0 (no confidence), 1 (low confidence or unsubstantiated) or 2 (substantiated or of high confidence) (see detailed protocol below).
The results of this recuration (Fig. 4a and Supplementary Table 1 online) showed that 25% of the sampled interactions could be substantiated whereas three-quarters were not. Of the interacting pairs in the sample, 35% were incorrectly curated. These observations explain the poor reliability, relative to high-throughput datasets, of the singly supported literature-curated dataset in both computational and experimental comparative analyses.

For human PPI recuration, we prepared two curation datasets. One was a presumed high-confidence literature-curated dataset of interactions (LC-multiple) within the initial search space of 7,000 genes for a first-draft human interactome mapping project corresponding to pairs reported two or more times (two different PubMed identifiers) and curated in two or more databases (the five databases used were HPRD, BIND, MINT, MIPS mammalian database and DIP). From within this small (275 multiply supported interactions) ‘hypercore’ set of protein interactions, 188 interactions were left for recuration, after excluding homodimers.

The other dataset was a lower-confidence literature-sampled dataset of 188 interactions, generated by randomly selecting interactions from the initial search space. Most of these interactions have one publication linked to the interaction, but because sampling was random, several interactions had been reported in more than one publication.

In the LC-multiple recuration set, 38% of the initial curation unit values (defined in Table 2) were wrong (Fig. 4b and Supplementary Table 2 online). The most common errors were wrong species (assignment to a species other than human (Box 1)) and absence of a binding experiment supporting the interactions. Although 40% of the human LC-multiple interactions were not supported by multiple publications after recuration, most of these interactions were supported in only one manuscript instead of two or more, perhaps constituting a ‘secondary’ dataset of reduced confidence (Supplementary Table 2).

For the presumably lower confidence literature-sampled dataset of 160 interacting pairs (after removing interactions that had more than one supporting publication), 45% of interactions were not validated (Fig. 4c and Supplementary Table 3 online) and 55% were validated. Almost half of the randomly sampled interactions were not supported by recuration. The most common errors here were wrong species and wrong protein name (Fig. 4c).

Yeast and human have the largest amount of curated literature in interaction databases. A model organism with fewer curated interactions might yield different results. We curated 100 higher-confidence protein interactions of Arabidopsis from the two interaction databases that curate Arabidopsis, TAIR and IntAct. The results were improved relative to the yeast or human results, as 6 interactions and 24 curation units were scored incorrect (Supplementary Table 4 online and Table 2). We scored the 24 errors as follows: 9 as ‘no binding experiment’; 6 as ‘no binding partner’; 6 as ‘indirect’; and 3 as ‘wrong protein’. The improved results for Arabidopsis likely reflect a smaller research community whose members can maintain uniformity in gene and protein names.

**Why is reliability of literature curation so low?**

Our findings of large error rates in curated protein interaction databases, at least for yeast and human, are consistent with recent hints that the quality of literature-curated datasets may not be as high as widely perceived. Perhaps occasionally curator error is responsible. However, we suggest that the errors are due not so much to curators but to the simple reality that extracting accurate information from a long free-text document can be extremely difficult. Gene name confusion is particularly thorny. An example from our curated yeast sample illustrates the difficulties. A purification with...
a tandem affinity purification tag with Vps71/Swc6 (slash separates synonymous approved names) as bait pulls down a protein named Swc3, but double-checking this finds that the corresponding open reading frame is actually SWC3 (locus name YAL011w), and not the ALR1/SWC3 (locus name YOL130w) open reading frame curated in the database. A shared synonym thoroughly muddled the curation.

Common curation practice has been to score equally every interaction reported in a publication, even though common experimental practice consists of first screening for new interacting proteins, then focusing on and substantiating one or a few of the most interesting interactions while leaving the others aside. Perhaps more curator judgment is needed, applying higher ranking to verified interactions and lower ranking to unverified 'along for the ride' interactions. Users can then choose the confidence level suitable to their needs. Given the demands of systems biology, perhaps biological databases should no longer serve as mere repositories of data but should appraise data. Recent small incremental steps at developing a confidence score for curated PPIs have been taken.

The difficulty of literature curation is often underappreciated. The lack of formal representation of PPIs in published manuscripts makes it difficult, if not impossible, to extract the PPI data in usable form. Designation of the species of origin of the protein interactors, an absolutely critical piece of information, is often buried or lacking altogether; protein or gene name synonyms used in a particular manuscript are hard to trace back to the canonical protein or gene names, especially in older manuscripts; and standardized descriptions, sometimes all description, of the methods used are absent. Faced with these difficulties, the curator is forced either to omit the information altogether (curated false negative) or make an educated guess, even though guesses, albeit educated ones, are often erroneous (curated false positive). The small overlaps noted between curated yeast interactions in different databases (Fig. 3) might be due to differential treatments of potential curated false negatives.

Our observations that literature-curated datasets have inherent reliability difficulties should influence thinking about proper generation of positive reference sets. Already the human positive reference sets generated in our sampled recuration efforts have proven useful in multiple investigations.

It is still rarely doubted that literature-curated interactions are better than datasets generated with any high-throughput technology. Our findings lead us to argue otherwise. If rigorously carried out, high-throughput experimental PPIs can be of higher quality than literature-curated interactions.

Improving reliability of literature-curated PPI datasets

The difficulty of curation arises partly because PPI data are not submitted to databases in standardized format upon publication, unlike DNA-sequence or protein-structure data. The difficulty that curators have in extracting PPI information from manuscripts has led to the promulgation of the minimal information about a molecular interaction experiment (MIMIx) initiative. MIMIx standardizes the presentation of PPI information in published manuscripts regarding species, protein names, methodological descriptions and protein identifiers, making it easier for curators to extract the pertinent information. Once widely promulgated, which should come about sooner if the structured digital abstract project gains traction, MIMIx will greatly improve curation such that the erroneous curation uncovered here will be lessened. Other minimal information initiatives for large-scale biology data are under development, and their development is wholeheartedly endorsed by the biocuration community so as to reduce curation error.

Our findings, although possibly critical of the quality of existing PPI curation, must not be used for quality evaluation of the underlying scientific literature. Actually, some PPI publications do warn of possible cross-contamination or even occasionally provide heuristic confidence scores, warnings that should be taken into account in the curation.

Curation protocols

Yeast PPI recuration. For each randomly selected protein pair, we read in detail the reporting manuscript (text, figures and supporting information), searching for all supporting information about the presumed interaction. We answered five questions for each protein pair. (i) Is there any information in the manuscript that supports the interaction? (ii) Has the experiment supporting the interaction been done at low throughput? As the perception persists that low-throughput experiments have greater reliability1, knowing this is important. (iii) Are the interacting proteins mentioned together in the text? Lack of co-citation indicates that the authors did not actually focus on that particular interaction. (iv) Is the interaction supported by multiple methods? (v) Is the interaction likely direct? That is, did the method(s) used gauge binary interaction or membership in the same complex? Lastly, we assigned to each interacting pair an overall score of 0 (no confidence: no mention of the interacting pair, negative answer to the other four questions), 1 (low confidence: interacting pair is mentioned but the interaction is not substantiated by alternative methods) or 2 (high confidence: multiple validations by alternative methods).

Two different curators independently curated and scored all interactions. A third independent curator resolved the few scoring conflicts.

Human PPI recuration. We compiled the human PPI dataset as previously described31. First, we classified the method codes used by each database as binary (for example, two hybrid methods) or indirect (for example, co-affinity purification)25. Then, we selected only protein interactions with binary support for subsequent analysis31. The multiply supported literature-curated dataset comprised 585 curation units (Table 2) representing 188 PPIs, each reported in two or more publications and curated in two or more PPI databases. The dataset randomly selected from the full human literature-curated dataset31 comprised 240 curation units representing 188 PPIs.

The types of information we collected during recuration were: the gene symbols and GeneID of each interactor; the associated PubMed identifier; the name and the identifier number of the interaction assay following the standard ‘interaction detection method’ vocabulary implemented in Proteomics Standards Initiative–Molecular Interactions34; the region of each protein used for the interaction assay following the standard ‘interaction detection method’ vocabulary implemented in Proteomics Standards Initiative–Molecular Interactions34; the region of each protein used for the interaction assay (marked full-length if the entire protein sequence was used); the species for each interacting protein; and clarifying free-text comments used by the curator when needed. Interpretative fields included; an assessment of whether the interaction was bona fide, that is, not erroneous; an assessment of whether the interaction was indeed binary; and an error field, using a simple controlled vocabulary to classify erroneous curation units such as ‘wrong protein’, ‘wrong species’, ‘no binding experiment’, ‘no binding partner’ (interaction between the proteins is not shown), ‘indirect’ (no direct interaction is shown), ‘redundant PubMed identifier’ (some manuscripts (usually crystallographic structure determination manuscripts) have two distinct PubMed identifiers

*For human a curation unit is an interaction reported in one publication regardless of the number of databases curating the interaction. An interaction reported in three distinct manuscripts and curated in two databases represents three curation units. For Arabidopsis a curation unit is an interaction reported in one publication or one database. An interaction reported in three distinct manuscripts and with all three curated in the two Arabidopsis PPI databases represents six curation units.

Figure 4 | Summary of recuration results. (a) Confidence scores of 100 interacting pairs randomly drawn from the yeast literature-curated dataset supported by only a single publication. numbers in PPI databases, and thus do not constitute two distinct manuscripts supporting an interaction).

If there was no information about the region of the protein responsible for the interaction, then the default we used was the full-length protein. If the species of the interacting proteins was not stated in a manuscript, a distressingly common occurrence, our default was to record the species as human. Thus, many interactions that did not involve human proteins might have been curated as human, so we may have underestimated the actual error rate. If the interaction was legitimate but one or the other protein partner was a species other than human, then we did not call this interaction bona fide. An interaction supported by multiple methods had to have just one bona fide and binary method to be recorded as legitimate; other methods apart from this one could be not binary or erroneous and not affect the final scoring.

Generally, we labeled yeast two-hybrid and other protein complementation assays as well as structural determinations as binary. We considered immunoprecipitation and co-affinity purification methodologies done in vivo that assess membership in the same complex not binary, whereas we considered those done in vitro with, for example, recombinant proteins as binary. If a tagged protein was heterologously expressed in a cell to pull down endogenous proteins, then we called such an interaction not binary. However, if both proteins of an interacting pair were heterologously expressed in a cell and shown to interact by, for example, pull down, then we considered such an interaction binary, as it is unlikely that an endogenous host protein mediates the interaction between the two heterologous proteins. If a co-immunoprecipitation done in vivo occurred in both orientations (protein A immunoprecipitation pulls down protein B and protein B immunoprecipitation pulls down protein A), then we judged this interaction as binary. As experimental procedures are often not described in sufficient detail to allow judgment of binary interaction, consistent policies in this regard were difficult to achieve.

Usually, we considered structural determinations to be binary, except for protein complexes of more than two proteins in which the interacting protein pairs did not actually contact each other in the solved structure. We scored solved structures that required a small third entity for crystal formation (for example, GTP, phosphatidylinositol) as binary, even though the interaction does not occur unless the small molecule is present.

A particular curation unit could have more than one error, though we counted only the most prominent error.

**Arabidopsis PPI recuration.** For Arabidopsis, we defined high-confidence interactions as those supported by two manuscripts or by two databases. In the initial search space of an ongoing Arabidopsis interaction mapping project, we collected 100 such interactions. We chose the union (or) instead of the intersection (and) for Arabidopsis, in contrast to human, so that a sufficiently sized sample of interactions was available. Otherwise, curation policies were as for human, including the error codes, but adding the name and the identifier of the ‘participant identification method’ vocabulary implemented in PSI-MI34.
